Abstract

LogicWeb mobile code consists of Prolog-like rules embedded in Web pages, thereby adding logic programming behaviour to those pages. Since LogicWeb programs are downloaded from foreign hosts and executed locally, there is a need to protect the client from buggy or malicious code. A security model is crucial for making LogicWeb mobile code safe to execute. This paper presents such a model, which supports programs of varying trust levels by using different resource access policies. The implementation of the model derives from an extended operational semantics for the LogicWeb language, which provides a precise meaning of *safety*.

1 Introduction

A significant development of the World Wide Web, which has attracted considerable interest in recent years, is the addition of *mobile code* to Web pages; Java applets and JavaScript are popular examples. Code of this kind adds sophisticated interactive behaviour to Web documents, allowing more useful tasks to be performed. However, a key issue is security, since mobile code is downloaded from foreign hosts and executed locally.

Malicious or buggy code can attack a local host in three main ways (Brown, 1996; Ousterhout *et al.*, 1997):

- *integrity attacks*: attempts to delete or modify information in the local environment in unauthorised ways. For example, a program issues an operating system command to delete local files.
- *privacy attacks*: attempts to steal or leak information to unauthorised parties. For example, a program reads a file and transmits the contents to another host.

* This author is grateful to Leon Sterling who (with Andrew Davison) co-supervised the work on which this paper is based.

- *denial of service attacks*: attempts to occupy resources to an extent which interferes with the normal operation of the host. An example is a program executing an infinite loop, resulting in CPU cycles wasted and a depleted heap space.

These attacks are only possible if a foreign program has unregulated access to local system resources such as the file system, network services (e.g., socket connections), CPU cycles, internal memory, input/output devices, the program environment (e.g., environment variables), and operating system commands. At the other extreme, a foreign program which is denied access to all resources cannot do any damage, but is unlikely to be able to do much useful work.

There is no one applicable policy for all foreign code: some code should be more trusted than others, and hence should be given more privileges. Providing a security model that provides the right level of functionality with the appropriate degree of security at the right time is a challenge. Indeed, security for mobile code is an active research area (Vitek & Tschudin, 1997; Brown, 1996; Cugola *et al.*, 1997; Thorn, 1997).

An emerging trend is the use of formal language semantics to reason with mobile code and prove security properties. For example, Leroy and Rouaix (1998) have developed formal techniques for validating a typed functional language with assignments, ensuring that memory locations always contain appropriate values. The use of a rewriting logic is advocated in (Meseguer & Talcott, 1997) as the basis for a mobile code programming language where security properties can be formally verified. Volpano (1997) argues for the development of provably-secure programming languages which can be remotely evaluated, and whose semantics permit the formal proof of security properties. As reported in (Dean *et al.*, 1996), a number of security loopholes have been discovered with Java applets, and this seems related to its lack of a formal semantics. Recently, this weakness has been addressed by giving semantics to subsets of Java (Drossopoulou & Eisenbach, 1998; Jensen *et al.*, 1998).

Declarative languages come with simple and elegant semantics, providing a convenient basis for reasoning about program execution and for introducing security mechanisms. This paper examines a security extension for a Prolog-based mobile code language called the LogicWeb language (Loke & Davison, 1998a). Underpinning the language is a view of the Web as a collection of logic programs called *LogicWeb programs*. LogicWeb clauses embedded within Web pages add logic programming behaviour to those pages. A LogicWeb program can retrieve and manipulate other Web pages (which may optionally contain embedded LogicWeb code themselves) using compositional logic programming techniques. Applications of LogicWeb include Web-based distributed deductive databases, and extending the semantics of Web links (Loke *et al.*, 1996b; Loke *et al.*, 1996a; Loke & Davison, 1997).

In this paper, we present a security model for LogicWeb which provides for the safe (i.e., host-protecting) execution of programs without overly restricting their capabilities. The key features of the model are:

- *flexible*: it supports varying degrees of trust and access to resources. More trusted programs can be given more privileges to achieve greater functionality. Policies determine what resources are available to whom, and how the resources must be used.
- *formally specified*: the model provides a precise meaning of *safety*.
- *implemented based on the model's specification*: the implementation takes the form of a meta-interpreter which is closely allied to the underlying operational semantics.

The security model is specified as an extension of the operational semantics of the LogicWeb language, and so permits a straightforward proof that the model protects the host according to specified policies. We describe how meta-programming provides the necessary control over execution behaviour for a flexible yet safe execution environment, including control over resource usage and looping. We also show how security policies can support different trust levels, and how policies can be combined to control the execution of an application composed from programs with different trust levels. The security model is implemented as an extension of the system described in (Loke & Davison, 1998b).

The rest of this paper is organised as follows. §2 provides background on LogicWeb, §3 gives an overview of the security model, §4 describes how we utilise digital signatures, and §5 examines how security policies are specified. The need to combine security policies during goal evaluation is explained in §6. §7 describes how policies are enforced by policy programs. An implementation of the security model is given in §8. Control of resource usage using meta-interpreters is illustrated in §9. §10 reviews related work, and §11 concludes.

2 Preliminaries

This section gives an overview of LogicWeb programs, the language, and the architecture of the client-side LogicWeb system.

2.1 LogicWeb Programs

LogicWeb programs are constructed from the data returned by HEAD, GET or POST HTTP requests. When successful, a HEAD request returns meta-information about a page, whereas GET and POST requests return meta-information *and* Web pages.

The LogicWeb program derived from a HEAD response consists of two types of facts for holding the page's meta-information and URL:

- `about(FieldName, Value)`. `about/2` facts store the page's meta-information as supplied by the server (e.g., the content length).
- `actual_url(URL)`. This holds the URL of the page whose meta-information was retrieved from the server. The actual URL would be different from the URL used in the original HTTP request if the request was redirected by the server.

The program corresponding to a HEAD response uses the identifier `lw(head, URL)`. Programs corresponding to GET and POST responses use `lw(get, URL)` and `lw(post(Data), URL)` respectively. A GET or POST response is translated into five types of facts based on the meta-information returned by the page's server and the HTML text in the page. Additional LogicWeb clauses may also be included within the page.

The facts include `about/2` and `actual_url/1` described above, and the following:

- `my_id(Type, URL)`. *Type* stores the type of the program, which is either the term `get` or `post(Data)`. *Data* is the information posted to the CGI script at *URL*.
- `h_text(HTMLText)`. This contains the HTML text of the page (apart from any additional LogicWeb clauses).
- `link(Label, URL)`. This stores a page's link information. For instance, the anchor:

```
...<A HREF="http://www.cs.mu.oz.au/">Melb. U</A>...
```

becomes:

```
link("Melb. U", "http://www.cs.mu.oz.au/").
```

Additional facts can be readily extracted from the text of the page, as described in (Loke & Davison, 1998b).

Clauses are included within a page between the tags “<LW_CODE>” and “</LW_CODE>”. Typically, the code appears inside a verbatim container “<PRE>...</PRE>” or a comment container “<!--...-->” so that it is uninterpreted by the browser. Figure 1 shows a page holding LogicWeb clauses about research interests.

`interested_in/1` defines the author's interests using Prolog-style facts and rules. The LogicWeb operator “#>” evaluates the `interested_in/1` goal against the program identified by `lw(get, URL)`.

Assuming that the page shown in Figure 1 was retrieved from `http://www.cs.mu.oz.au/~swl/` using the GET method, then the resulting LogicWeb program contains:

1. Several `about/2` facts concerning the page's meta-information.
2. `actual_url("http://www.cs.mu.oz.au/~swl/").`
3. `my_id(get,"http://www.cs.mu.oz.au/~swl/").`
4. `h_text("<HTML>...</HTML>").` This fact stores all the HTML text from the page except the clauses between the “<LW_CODE>” and “</LW_CODE>” tags.
5. Two `link/2` facts:

```
link("Department of Computer Science", "http://www.cs.mu.oz.au/").
link("University of Melbourne", "http://www.unimelb.edu.au/").
```

6. The clauses between the “<LW_CODE>” and “</LW_CODE>” tags.

A *LogicWeb application* comprises a set of LogicWeb programs, with one singled out (by the programmer) as the *main program*. Each application has an *identity*

which is the program identifier of the main program, and a *visible interface* with which the user interacts. A typical interface consists of a HTML form and/or Web links. Clauses in the main program define the forms interface and the mapping of link selections to goals.

2.2 The LogicWeb Language

The LogicWeb language utilises Prolog and special LogicWeb operators. We will assume that the reader is familiar with Prolog, and concentrate instead on the operators.

2.2.1 LogicWeb Operators

A *LogicWeb goal* is formed using the operator “#>”, which is known as *context switching*. For example, the LogicWeb goal `lw(get, URL)#>Goal` applies `Goal` to the program specified by the `lw(get, URL)` identifier.

If the program is not already present on the client-side, then its page will be downloaded and translated into a LogicWeb program before the query is evaluated. However, if the program is present, then the goal is executed immediately. Thus, the “#>” operator permits the programmer to think of Web computation as goals applied to programs, with no need for explicit Web page retrieval, parsing, or storage.

The current context of a LogicWeb goal, i.e. the program (or composition of programs) where the goal is located, is ignored when “#>” is evaluated.

LogicWeb programs can be manipulated using five *LW-composition operators*. Four are based on Brogi’s algebraic program composition framework (Brogi, 1993), and the fifth on *reduce* from functional programming. The operators are: *LW-union* (“+”), *LW-intersection* (“*”), *LW-restriction* (“/”), *LW-encapsulation* (“@”), and *LW-reduce* (“<>”). An expression formed with LW-composition operators is called a *program expression*.

LogicWeb programs are composed together after they have been retrieved from the Web, which means that the semantics of the operators can be viewed as a variant of Brogi’s definitions, extended to address issues related to page downloading and the translation of pages to programs. The operational semantics are specified in §2.2.3.

The sixth operator, the *context* operator, denoted by “(#)”, represents the current context in a program expression. For instance:

```
?- lw(get, "URL0")#>((#) + lw(get, "URL1"))#>interested_in(X).
```

“(#)” is instantiated to `lw(get, "URL0")` when the goal is evaluated. “(#)” can be used in place of a program identifier in any expression, which provides very useful expressive power. For instance, it can readily model other composition formalisms (Loke & Davison, 1998a).

2.2.2 EBNF Syntax

A *pure* LogicWeb program is a finite set of clauses of the form $[\forall x](\mathcal{A}:-\mathcal{G})$ where \mathcal{G} is defined recursively as:

$$\mathcal{G} ::= \mathcal{A} \mid \mathcal{E} \# \mathcal{G} \mid (\mathcal{G}, \mathcal{G})$$

\mathcal{E} defines LogicWeb program expressions:

$$\begin{aligned} \mathcal{E} &::= \mathcal{P} \mid \mathcal{E} + \mathcal{E} \mid \mathcal{E} * \mathcal{E} \mid \mathcal{E} / \mathcal{P} \mid @E \mid (/) <> (\mathcal{E}, \mathcal{L}_{(\mathcal{P})}) \mid (\oplus) <> \mathcal{L}_{(\mathcal{E})} \\ \mathcal{P} &::= \text{lw}(\text{head}, URL) \mid \text{lw}(\text{get}, URL) \mid \text{lw}(\text{post}(\mathcal{L}_{(\mathcal{F})}), URL) \mid (\#) \\ \mathcal{F} &::= \text{field}(Name, Value) \\ \mathcal{L}_{(\mathcal{I})} &::= [] \mid [\mathcal{I} \mid \mathcal{L}_{(\mathcal{I})}] \\ \oplus &::= + \mid * \end{aligned}$$

$\mathcal{L}_{(\mathcal{I})}$ defines a Prolog list of items, each of which is described by a nonterminal \mathcal{I} . *URL* is a URL, and \mathcal{F} a query attribute submitted to a CGI script. *Name* is the name of a query attribute, and *Value* is the value submitted to the server for the corresponding attribute. The context operator “(#)” can appear anywhere a program identifier can, but must be instantiated to a program identifier when used as the right-hand argument of LW-restriction.

2.2.3 Operational Semantics

The operational semantics of the LogicWeb language is detailed in (Loke & Davison, 1998a), but so that this paper is self-contained, the semantics are summarised here. In particular, we do not consider LW-restriction and LW-reduce.

An *oracle function* is defined to model the accessing of LogicWeb programs.

Definition 2.1 (oracle function)

The oracle function

$$\text{download} : LWProgramIDs \rightarrow LWPrograms \cup \{\perp\}$$

takes a LogicWeb program identifier P (of the form defined by \mathcal{P}), and returns the program D_P if it is successfully created. Failure to obtain a program is represented by returning the symbol \perp .

$$\text{download}(P) = \begin{cases} D_P & \text{if the program denoted by identifier } P \text{ is} \\ & \text{successfully created,} \\ \perp & \text{otherwise.} \end{cases}$$

download attempts to download a HTTP response object and translate it into a LogicWeb program in the way specified in §2.1.

The set of downloaded programs is extended by calling the function *add_programs*, which takes the set of existing LogicWeb programs and maps it to a new set using *download*.

Definition 2.2 (addition of LogicWeb programs)

Let \wp denote powerset. The function

$$\text{add_programs} : \wp(LWPrograms) \times \wp(LWProgramIDs) \rightarrow \wp(LWPrograms)$$

takes a set S of programs and a set I of program identifiers and returns a new set $\text{add_programs}(S, I)$ consisting of S augmented with newly created programs mentioned in I but previously not in S :

$$\text{add_programs}(S, I) = S \cup \{D_P \mid P \in (I \setminus \text{ids}(S)), D_P = \text{download}(P), D_P \neq \perp\}$$

where *ids* is a function that takes a set of programs and returns the identifiers of the programs in the set, i.e. $\text{ids}(S)$ is the set of identifiers of the programs in S .

A derivation relation involving the set of downloaded LogicWeb programs specifies the computation model involving interactions with the Web.

Definition 2.3 (derivation relation)

For any goal formula G and program expression E , we denote by $S, E \vdash_\theta^{S'} G$ the fact that there exists a top-down derivation of G in E starting with the set S of existing LogicWeb programs and ending with computed answer substitution θ and created program set S' . A top-down derivation or proof of G in E starting with S and ending with S' and θ is a finite tree such that:

1. the root node (bottom node) is labelled by the string “ $S, E \vdash_{\theta}^{S'} G$ ”;
2. the internal nodes are derived according to the set of inference rules given below; and
3. all the leaves of the tree are either empty or labelled by a string not containing the symbol “ \vdash ” (e.g., the label “ $(A : -G) \in P$ ”).

\vdash_{θ}^S is defined to be the smallest relation satisfying the inference rules below. If $S, E \vdash_{\theta}^{S'} G$, then the goal G succeeded when evaluated in E using S . Otherwise, the goal G failed when evaluated in E using S .

Given a top-down derivation $S, E \vdash_{\theta}^{S'} G$, if the derivation does not involve interactions with the Web or if no programs are downloaded, then S' is the same as S (i.e., $S' = S$). If programs are downloaded, then S is extended to S' ($\supseteq S$). The difference $S' \setminus S$ represents the effect of Web interactions during the derivation.

A context is defined for each node in a top-down derivation whose label is of the form “ $S, E \vdash_{\theta}^{S'} G$ ”.

Definition 2.4 (context of a goal)

Given the node label “ $S, E \vdash_{\theta}^{S'} G$ ”, E is the context (of G).

In the rules, P denotes single program identifiers of the form \mathcal{P} , and E and F denote program expressions of the form \mathcal{E} as defined in §2.2.2. $L_{(\mathcal{I})}$ denotes a list of the form $\mathcal{L}_{\mathcal{I}}$. ϵ denotes the empty (identity) substitution.

The following rules define derivation in pure Prolog taking into account the creation of LogicWeb programs:

True.

$$\frac{}{S, E \vdash_{\epsilon}^S \text{true}} \quad (1)$$

true is always derivable in any program expression E without any change to the set of created programs.

Conjunction.

$$\frac{S, E \vdash_{\theta}^{S'} G_1 \quad \wedge \quad S', E \vdash_{\gamma}^{S''} G_2 \theta}{S, E \vdash_{\theta\gamma}^{S''} G_1, G_2} \quad (2)$$

S' , which may or may not be the same as S , is the result of Web interactions from G_1 's derivation. The result of these interactions are propagated to G_2 by starting the derivation of $G_2\theta$ with S' . Since $G_2\theta$ started with S' , S'' is the result of Web interactions during the derivation of the conjunction.

Atomic formula.

$$\frac{S, E \vdash_{\theta}^{S'} (H : -G) \quad \wedge \quad \gamma = mgu(A, H\theta) \quad \wedge \quad S', E \vdash_{\delta}^{S''} G\theta\gamma}{S, E \vdash_{\theta\gamma\delta}^{S''} A} \quad (3)$$

Obtaining clauses from E can involve the creation of new programs due to LW-encapsulation (see rule (8)), and so, S is changed to S' . The proof of the body starts with the computed program set S' and returns the new set S'' and the answer substitution δ .

Obtaining clauses from a single program.

$$\frac{(A :- G) \in P}{S, P \vdash_{\epsilon}^S (A :- G)} \quad (4)$$

The answer substitution is ϵ , and there is no change to S .

Below, we present the rules for choosing clauses from LW-union, LW-intersection, LW-encapsulation, and context switching.

LW-union.

$$\frac{S, E \vdash_{\theta}^{S'} (A :- G)}{S, E+F \vdash_{\theta}^{S'} (A :- G)} \quad (5)$$

$$\frac{S, F \vdash_{\theta}^{S'} (A :- G)}{S, E+F \vdash_{\theta}^{S'} (A :- G)} \quad (6)$$

A clause is chosen from a LW-union $E+F$ by choosing a clause from either E or F .

LW-intersection.

$$\frac{S, E \vdash_{\theta_1}^{S'} (H_1 :- G_1) \quad \wedge \quad S', F \vdash_{\theta_2}^{S''} (H_2 :- G_2) \quad \wedge \quad \gamma = mgu(H_1\theta_1, H_2\theta_2)}{S, E*F \vdash_{\theta_1\theta_2\gamma}^{S''} (H_1 :- G_1, G_2)} \quad (7)$$

A clause $H :- G$ is obtained from the LW-intersection $E*F$ if there exists a clause $H_1 :- G_1$ in E and a clause $H_2 :- G_2$ in F such that H unifies with H_1 and H_2 , and $G = (G_1, G_2)$. This rule utilises a left-to-right ordering in choosing clauses from $E*F$. Rules are first chosen from E returning S' , and then, S' is used when selecting clauses from F ending up with S'' .

LW-encapsulation.

$$\frac{S, E \vdash_{\theta}^{S'} A}{S, \mathbb{Q}E \vdash_{\theta}^{S'} A :- \text{true}} \quad (8)$$

A clause $A :- \text{true}$ is obtained from the encapsulation of E , $\mathbb{Q}E$, if A is provable in E . LogicWeb programs can be created in the proof of A , i.e. a new program set S' is computed starting with S .

Context Switching. We first define the function

$$\text{expids} : \text{ProgramExpressions} \rightarrow \wp(\text{LWProgramIDs})$$

to refer to the program identifiers within a program expression. *expids* is defined recursively based on the syntax of program expressions:

$$\begin{aligned}
\text{expids}(P) &= \{P\} \\
\text{expids}(E_1 + E_2) &= \text{expids}(E_1) \cup \text{expids}(E_2) \\
\text{expids}(E_1 * E_2) &= \text{expids}(E_1) \cup \text{expids}(E_2) \\
\text{expids}(E / P) &= \text{expids}(E) \cup \text{expids}(P) \\
\text{expids}(\textcircled{E}) &= \text{expids}(E) \\
\text{expids}((/) \langle \rangle (E, L_{(\mathcal{P})})) &= \text{expids}(E) \cup \text{expids}(L_{(\mathcal{P})}) \\
\text{expids}((\oplus) \langle \rangle L_{(\mathcal{E})}) &= \text{expids}(L_{(\mathcal{E})}) \\
\text{expids}(L_{(\mathcal{E})}) &= \bigcup_{E \in L_{(\mathcal{E})}} \text{expids}(E)
\end{aligned}$$

In the above, we have used \in to represent list membership, and a $L_{(\mathcal{P})}$ is a $L_{(\mathcal{E})}$ from the EBNF definition in §2.2.2.

We also define the function:

$$\text{insertCC} : \text{ProgramExpressions} \times \text{ProgramExpressions} \rightarrow \text{ProgramExpressions}$$

which substitutes every occurrence of the operator $\#$ in a program expression (the first argument) with the current context (the second argument):

$$\begin{aligned}
\text{insertCC}(\#, C) &= C \\
\text{insertCC}(P, C) &= P \\
\text{insertCC}(E_1 + E_2, C) &= \text{insertCC}(E_1, C) + \text{insertCC}(E_2, C) \\
\text{insertCC}(E_1 * E_2, C) &= \text{insertCC}(E_1, C) * \text{insertCC}(E_2, C) \\
\text{insertCC}(E / P, C) &= \text{insertCC}(E, C) / \text{insertCC}(P, C) \\
\text{insertCC}(\textcircled{E}, C) &= \textcircled{\text{insertCC}(E, C)} \\
\text{insertCC}((/) \langle \rangle (E, L_{(\mathcal{P})}), C) &= (/) \langle \rangle (\text{insertCC}(E, C), \text{insertCC}(L_{(\mathcal{P})}, C)) \\
\text{insertCC}((\oplus) \langle \rangle L_{(\mathcal{E})}, C) &= (\oplus) \langle \rangle \text{insertCC}(L_{(\mathcal{E})}, C) \\
\text{insertCC}(L_{(\mathcal{E})}, C) &= [\text{insertCC}(E, C) \mid E \in L_{(\mathcal{E})}]
\end{aligned}$$

The rule defining context switching is the following:

$$\frac{I \subseteq \text{ids}(S') \quad \wedge \quad S', F' \vdash_{\theta}^{S''} G}{S, E \vdash_{\theta}^{S''} F \# G} \quad (9)$$

where $F' = \text{insertCC}(F, E)$, $I = \text{expids}(F)$, and $S' = \text{add_programs}(S, I)$.

The rule states that the goal $F \# G$ is provable in E starting with the program set S if the goal G is provable in F' starting with the updated program set S' which contains all the programs mentioned in I (and hence, in F).

2.3 The LogicWeb System Architecture

The architecture of the LogicWeb system (its components and data-flows) is shown in Figure 2.

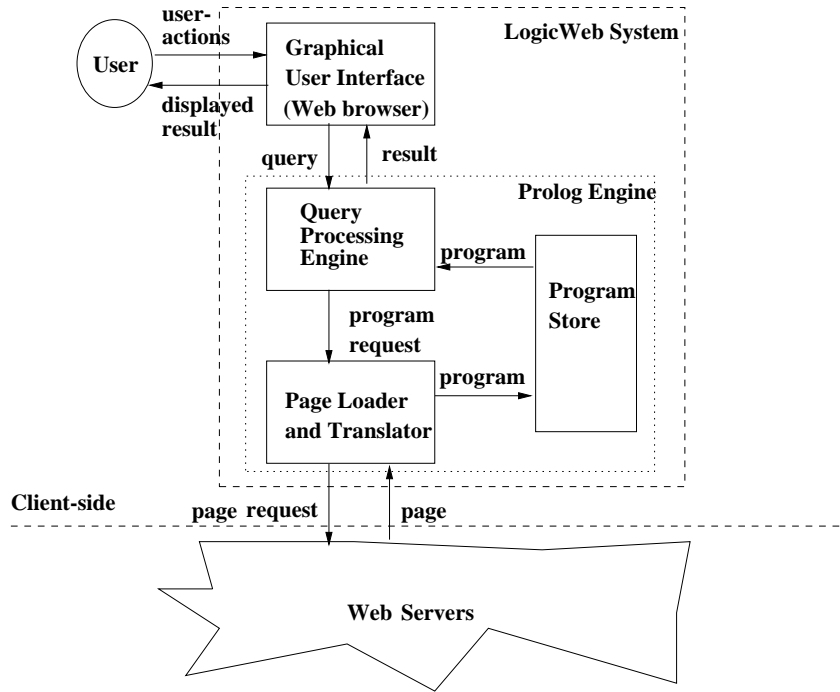

Fig. 2. Architecture of the LogicWeb system.

The main components are:

- a graphical user interface (GUI);
- an engine for processing user queries;
- a page loader and (page to program) translator; and
- a store of LogicWeb programs.

The Prolog engine consists of three components: the query processing engine, the program store, and the page loader and translator. The query processing engine consists of the LogicWeb program interpreter (see §8.1) and predicates to translate user actions into the evaluation of specific goals in LogicWeb programs. Downloaded LogicWeb programs are stored inside the program store (actually as facts in a SWI-Prolog database). The page loader and translator consist of predicates which download and parse HTML documents to extract the clauses making up LogicWeb programs.

The system converts a user action (i.e., link selection or form submission) into a query. It computes the result of the query with respect to a program by invoking the LogicWeb interpreter. Processing of the query may result in other pages being downloaded and translated into LogicWeb programs. When query processing ends, the system formats the result and shows it to the user via the browser.

The above architecture has been implemented using the NCSA Mosaic browser and SWI-Prolog (for the Prolog engine). The two are integrated with Mosaic's

Common Client Interface (CCI) API (Loke & Davison, 1998b). This implementation is extended in §8.

3 Overview of the Security Model

The LogicWeb security model assumes the following about the downloading and execution of programs:

- Program *source* is downloaded. Since the local host receives the source rather than a compiled form (e.g., binaries or bytecode), each goal is visible at the interpreter level. Also, if the source is unencrypted then it is open to tampering – it may be intercepted during transmission and modified.
- Downloaded programs are executed by an interpreter based on the operational semantics presented earlier. Such an interpreter is described in (Loke & Davison, 1998b), and is extended in §8.
- A LogicWeb program can invoke goals in other programs. Therefore, the model must handle communication between programs possessing different levels of trust. A less trusted program should not be able to use the privileges of a more trusted program.

We have adopted a *sandbox* model, where each program is executed in a controlled space, limiting its access to resources and controlling the resources used. A sandbox for a LogicWeb program consists of its interpreter and a *security policy*, or *policy* for short, which controls the program's utilisation of system resources. A less trusted LogicWeb program is assigned a policy which restricts resource usage, while a more trusted program is granted a more liberal policy. Security policies are defined by each user of the LogicWeb system.

A LogicWeb program accesses the local environment and system resources via *system calls*, which are SWI-Prolog and LogicWeb built-in predicates. LogicWeb built-ins include predicates for displaying pages, constructing and parsing HTML documents, fast string matching, checking if a particular program exists in the program store, and deleting programs from the program store.

A policy specifies what system calls are permitted, and the ways they can be used. This information is encoded as a set of predicates in a *policy program* created by the LogicWeb system user. A policy program also states what programs can be utilised via context switching. Policy programs may be stored at remote sites or locally as long as they are protected from tampering. They can be integrated into the system using the same downloading mechanism as the rest of the LogicWeb system, including the use of composition to combine policies.

Assignment of policies to LogicWeb programs is *owner-based*. The choice of policy program assigned to a LogicWeb program is determined by how much the LogicWeb program is trusted which, in turn, depends on the owner of the program. The owner is identified by a mechanism external to the LogicWeb language, by authenticating the LogicWeb program using a PGP (Pretty Good Privacy) digital signature (Garfinkel, 1995).

Policy programs restrict the use of system calls, thereby preventing integrity and privacy attacks. Denial-of-service attacks are addressed by controlling the use of resources using policy programs (as shown in §9.1) and meta-interpreters (discussed in §9.2).

4 Digital Signatures for LogicWeb Programs

Information can be encrypted in PGP using a secret *private key*, and decrypted using a corresponding *public key* which is distributed publically. PGP keys are used for *authentication* in the following way. Suppose A encrypts a message and sends it to B. B wants to ensure that the encrypted message is really from A, and that the message has not been tampered with. To do this, B attempts to decrypt the message using A's public key. If the decryption succeeds, it means that the message was encrypted using A's private key and that it has not been modified. Also, since the key is only known to A, the message must have come from A. If the decryption fails, B cannot conclude that A encrypted the message.

PGP keys can also be used to *sign* documents or programs. Figure 3 shows the use of a digital signature when downloading a program from A to B, and the process of assigning a policy program. A PGP digital signature is created by first mapping the program to a string (actually, a single large number) using the MD5 algorithm (Garfinkel, 1995), which almost uniquely identifies the message.¹ The MD5 string is then encrypted using the sender's private key, and this encrypted MD5 string becomes the digital signature. The receiver of a signed program (the program and its signature) uses the sender's public key to decrypt the signature, producing the original MD5 string and the PGP ID. The receiver then checks that the program corresponds to the MD5 string, i.e. the program has not been modified in any way, and assigns a policy to the program by consulting a database maintained in the system which maps PGP IDs to policy program IDs. Note that the system uses three kinds of IDs: PGP IDs, policy program IDs and IDs of an application's LogicWeb programs, and that since policy programs are LogicWeb programs, policy program IDs are LogicWeb program IDs. Unsigned programs, or programs where authentication failed, should not be trusted, and are given restricted access to system resources. The system stores the downloaded program, and records the policy assignment for later use in query evaluation. Policy programs not already present in the system are downloaded during query evaluation. §8 provides details on policy assignment and use.

A digital signature proves who sent the program, and that the program was not altered either by error or design. The signature also provides non-repudiation, which means that the sender cannot easily disavow his signature on the program.

One reason for using an MD5 string is that it is faster to encrypt and decrypt than the entire program. Also, since the program is not encrypted, the program source is

¹ In theory, two different messages could map to the same MD5 string, although this has never been known to occur (Garfinkel, 1995).

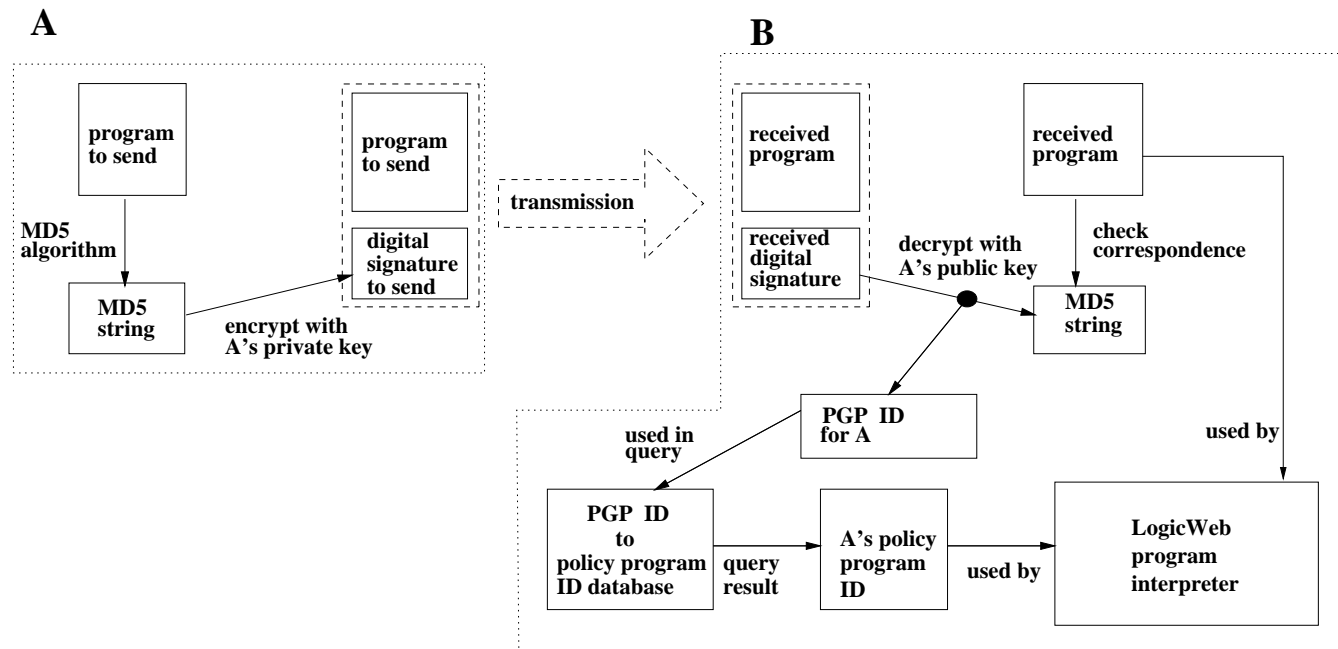

Fig. 3. Downloading a program from A to B, and the subsequent assignment of a policy program.

available even if authentication fails, and so can still be executed (though with limited privileges). However, if program confidentiality is required during transmission, the code can be encrypted.

We utilise PGP since it is difficult to break, equipped with public and private keys generation, widely available, supported on a range of operating system platforms, and one of the most popular encryption techniques. PGP public keys can be obtained either through personal communication between the LogicWeb system user and program owners, or via the Web: PGP public keys are increasingly being placed on homepages, where they can be readily retrieved by the LogicWeb system. The distribution of PGP keys is discussed further in §11.

5 Specifying Security Policies

A LogicWeb program accesses system resources via system calls *and* context switching. The resources used via context switching are socket connections for downloading pages and local storage for programs.

A policy program defines three predicates for controlling the system calls and context switching of its designated LogicWeb programs. The predicates are:

- `valid_program(Type, URL)`: this predicate specifies the LogicWeb programs which can be used via context switching. For example, restricting programs to those from the domain `www.cs.mu.oz.au` is given by:

```
valid_program(get, URL) :- contains(URL, "http://www.cs.mu.oz.au/").
```

The following query will fail when using that policy since the goal refers to an invalid domain:

```
?- lw(get, "http://www.cs.rmit.edu.au/")#>h_text(Src).
```

- `valid_systemCall(Call)`: this predicate defines the set of system calls a program is allowed to invoke. `Call` is a term representing the form the system call may take.
- `call_system(Call)`: this predicate is a wrapper for the allowed predicates defined by `valid_systemCall/1`. `Call` is a term representing the goal which is to be invoked in a special way. Typically, `call_system/1` is used to implement more restrictive versions of system calls.

The difference between `valid_systemCall/1` and `call_system/1` is *execution*. Call patterns specified in `valid_systemCall/1` are used to *test* system calls, rejecting ones which do not match the necessary requirements. `call_system/1` is used to *execute* system calls in novel (usually restricted) ways. A policy program could be written with the body code of `valid_systemCall/1` implemented in `call_system/1`, doing away with the need for the `valid_systemCall/1` predicate. However, the distinction between testing and execution would then be much less clear.

The following policy program permits the retrieval (using the GET method) of all URLs except `http://www.cs.mu.oz.au/~swloke/private.html`. It disallows all calls to `system/1` and `open/3`, except when `open/3` reads `dump.txt`:

```

valid_program(get, URL) :-
    URL \== "http://www.cs.mu.oz.au/~swloke/private.html".

valid_systemCall(open('/home/pgrad/swloke/lws/dump.txt', read, S)).
valid_systemCall(Call) :-
    Call \= open(_, _, _),
    Call \= system(_).

call_system(Call) :-
    built_ins:call_builtin(Call).

call_builtin/1 is a system predicate which carries out type checking on a call
before executing it. For example, the call_builtin/1 clause for open/3 is:

call_builtin(open(FileName, Mode, Stream)) :-
    atom(FileName),
    ( Mode = read
    ; Mode = write
    ),
    var(Stream),
    open(FileName, Mode, Stream).

```

FileName must be an atom, Mode either read or write, and Stream a variable. Type checking increases the robustness of the system by preventing instantiation faults when the arguments are the wrong type.

We briefly consider two examples that show the flexibility of security policies.

5.1 A Historical Policy

State information can be used to implement a history-based policy. For example, the following policy lets a program carry out context switching (i.e. execute goals such as `lw(get, URL)#>Goal`) until a file is accessed. A file access is detected by having `call_system/1` monitor `open/3` calls.

```

file_accessed(no).           % state information: no file has been accessed

valid_program(_, _) :-      % only context switch when no
    file_accessed(no).      % files have been accessed

call_system(Call) :-        % process non-open/3 calls
    Call \= open(_, _, _),
    built_ins:call_builtin(Call).

call_system(open(F, R, S)) :- % process open/3 call
    built_ins:call_builtin(open(F, R, S)),
    (file_accessed(no) ->
        retract(file_accessed(no)), % record file access
        assert(file_accessed(yes))
    );
    true
).

```

Once `open/3` has been called, `file_accessed/1` will be changed to hold the value `yes`. This will cause subsequent calls to `valid_program/2` to fail, disabling context switching for the program.

5.2 Levels of Trust

It is straightforward to build policies with varying levels of trust for different programs. In the following example we use three levels: dangerous, ok, and safe. A ‘dangerous’ program cannot download any programs, or execute any system calls. An ‘ok’ program can download programs but it can only write to the directory /tmp and cannot use `system/1` to delete files. A ‘safe’ program has no restrictions placed upon it, except that a message is printed out when a file deletion succeeds. Each level of trust is represented by a separate policy program.

The policy program for ‘dangerous’:

```
valid_program(_, _) :- fail.
```

```
valid_systemCall(_) :- fail.
```

```
call_system(_) :- fail.
```

Any call that uses system resources will fail.

The policy program for ‘ok’ is given as:

```
valid_program(_, _) .                % no restrictions on downloads
```

```
valid_systemCall(open(Path, write, _)) :-
```

```
!, append("/tmp/", _, Path).          % only write to /tmp
```

```
valid_systemCall(system(Cmd)) :-
```

```
append("rm ", _, Cmd), !, fail.      % disallow file deletions
```

```
valid_systemCall(_).                  % everything else allowed
```

```
call_system(Call) :-                  % no restrictions on execution
```

```
built_ins:call_builtin(Call).
```

The policy program for ‘safe’:

```
valid_program(_, _) .                % no restrictions on downloads
```

```
valid_systemCall(_).                  % all system calls permitted
```

```
call_system(Cmd) :-
```

```
built_ins:call_builtin(Cmd),
```

```
(append("rm ", _, Cmd) ->          % report deletions when executed
```

```
report_deletion(Cmd)
```

```
;
```

```
true
```

```
).
```

We could call `report_deletion/1` in `valid_systemCall/1` but reporting a file deletion has nothing to do with testing the validity of a system call; it is a diagnostic associated with execution.

6 Combining Security Policies

A LogicWeb program must not be allowed to perform an illegal system operation by invoking a goal in a more privileged program. Hence, the security model must ensure the following:

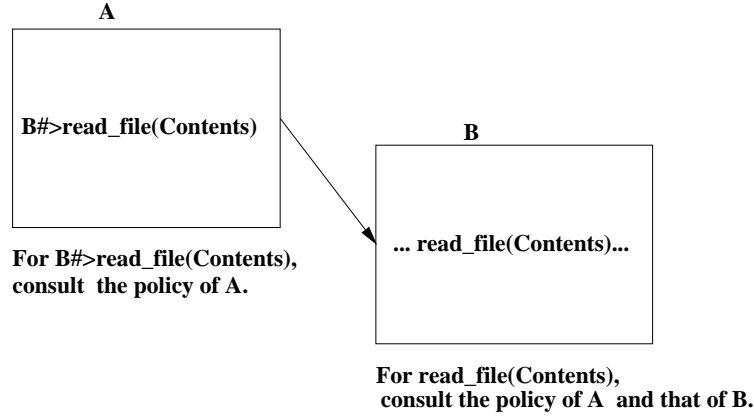

Fig. 4. The invocation of `B#>read_file(Contents)` in A.

1. *Context switching must not transfer privileges between programs.* The system has to ensure that an untrusted program does not illegally access resources by invoking a goal in a trusted program. For example, assume that a program P is not allowed to read a file (as determined by its policy) while another program Q can (as determined by Q's policy). This means that P should not be able to call a goal like `Q#>read_file(Contents)` to read a file. Clearly, it is too simplistic to validate a call to `read_file/1` in Q using only the policy of Q; the policy of P must also be considered.

In a similar manner, a LogicWeb goal cannot be allowed to perform an illegal system operation because it is invoked in a trusted program. For example, if A can read a file which B can not, then the goal `B#>read_file(Contents)` invoked in A should fail. This means that although A uses B, A should not pass its privileges to B, since the system trusts A but not B. Hence, the policies of both A and B must be consulted to determine if a `read_file/1` call should be allowed, as Figure 4 illustrates.

When more than two programs are involved, a similar but slightly more complex situation arises. For example, consider a goal `B#>(C#>G)` invoked in the program A, where G is a system call. If G is allowed by the policies of A and C, but B does not permit G, then B is performing an illegal system operation through C.

Essentially, disregarding any one of the policies potentially allows an illegal system operation. This means that to determine if G should be allowed, *all* the policy programs used by the code must be considered.

Figure 5 shows the changes in goal evaluation contexts starting from the goal `B#>(C#>G)` in program A and ending with goal G in C. The policies of all the programs involved in the evaluation of the goal starting from the first program (i.e., A) are required. Hence, the proof rules for the security model must incorporate a notion of the *current* set of policy programs which grows as goal evaluation progresses.

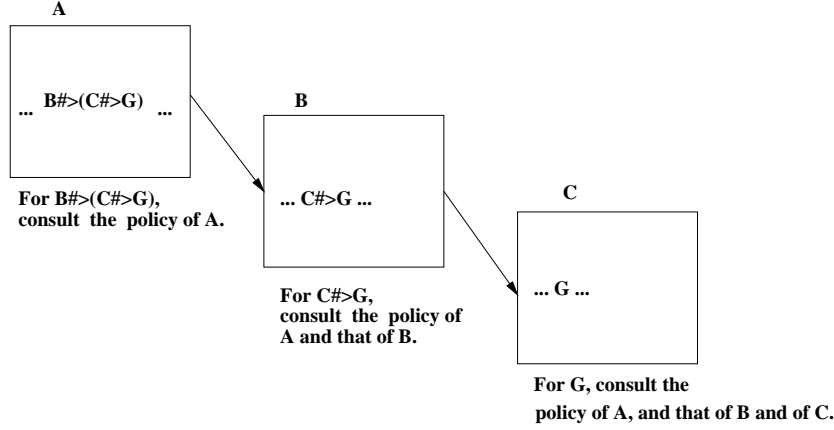

Fig. 5. The evaluation $B\#>(C\#>G)$ in program A.

2. *LW-compositions must not transfer privileges between programs.* A LogicWeb program can invoke the clauses of another program in a LW-composition. For example, consider a goal G evaluated in the LW-composition of programs S and T : $(S + T)\#>G$. G 's evaluation may utilise some clauses from S and some from T , so in general G must be allowed by *both* the policies for S and T .

The observations made above can be made more formal by restating them using the LW-encapsulation and LW-intersection operators ($@$ and $*$). Namely, given a set of policies (e.g., $\{P, Q\}$), the allowable set of system calls and downloads are those permitted by the composition $@P * @Q$.

LW-encapsulation is used to express that each policy must separately validate the system calls and downloads. LW-intersection is used to represent that a given system call or download must be permitted by *every* policy program. For example, an `open/3` call is permitted by both P and Q when the following goal succeeds:

```
?- (@P * @Q)#>valid_systemCall(open(_,_)).
```

7 Enforcing Security Policies

This section defines a new derivation relation, extending the operational semantics in §2.2.3 to use policy programs. Previously, a goal was evaluated in the current context, with the current set of created programs. In the new derivation relation, we also consider the current set of policy programs. The derivation relation is extended as follows:

For any goal formula G and program expression E ,

$$\Sigma, S, E \vdash_{\theta}^{S'} G$$

denotes the fact that there exists a *top-down derivation* of G in E starting with the set S of existing LogicWeb programs and the *ordered* set of policy programs Σ , and ending with the computed answer substitution θ and created program set S' .

The proof rules which define this new relation are an extension of the rules in §2.2.3. Rules (1) to (8) are modified to form corresponding rules for the new derivation relation by using the following syntactic mapping:

Replace every occurrence of an expression involving the derivation relation:

$$S, E \vdash_{\theta}^{S'} G$$

with the corresponding expression:

$$\Sigma, S, E \vdash_{\theta}^{S'} G$$

For instance, the following rule is obtained by applying this mapping to rule (2) (conjunction):

$$\frac{\Sigma, S, E \vdash_{\theta}^{S'} G_1 \quad \wedge \quad \Sigma, S', E \vdash_{\gamma}^{S''} G_2 \theta}{\Sigma, S, E \vdash_{\theta\gamma}^{S''} G_1, G_2}$$

The same set of policy programs Σ is used for each of the conjuncts since they occur in the same rule (and hence, in the same program).

7.1 Mapping from Programs to Policies

To aid the discussion which follows, two functions are defined: one maps a LogicWeb program to its policy program, and the other relates a set of LogicWeb programs to their policy programs. Φ denotes the set of all policy programs used by the system.

A policy program is permitted free access to system resources, and is not itself assigned a policy program.

Definition 7.1 (policy program assignment)

The function

$$pol : (LWProgramIDs \setminus ids(\Phi)) \rightarrow \Phi$$

takes a program identifier (which is not that of a policy program) and returns a policy program for that program from Φ .

pol is not defined on policy programs, and the empty program ξ is not assigned a policy program.

Definition 7.2 (policies for a set of programs)

The function

$$pols : \wp(LWProgramIDs \setminus ids(\Phi)) \rightarrow \wp(\Phi)$$

takes a set of (non-policy) program identifiers I and returns the set of policy programs assigned to the programs in I . $pols$ is defined by:

$$pols(I) = \{pol(i) \mid i \in I\}$$

7.2 Context Switching Revisited

$*\Sigma^{\circ}$ denotes the LW-intersection of the LW-encapsulation of the policy programs in Σ (i.e., if $\Sigma = \{P_1, \dots, P_n\}$ then $*\Sigma^{\circ} = @P_1 * \dots * @P_n$), and G denotes a goal. Evaluating a goal against $*\Sigma^{\circ}$ has the effect of evaluating the goal against each program in Σ separately.

The new definition of the context switching rule (9) is:

$$\begin{array}{c}
 \Sigma \neq \emptyset \quad \wedge \\
 \left\{ \begin{array}{l}
 \text{Where each } \text{lw}(\text{Type}i, \text{URL}i) \in \text{expids}(F') \setminus \text{ids}(\Phi), \\
 \emptyset, S, \xi \vdash_{\gamma}^{S'} * \Sigma^{\circ} \# \langle \text{valid_program}(\text{Type}1, \text{URL}1), \\
 \dots, \text{valid_program}(\text{Type}N, \text{URL}N) \rangle \quad \wedge \\
 I \subseteq \text{ids}(S') \quad \wedge \quad (\text{pols}(I \setminus \text{ids}(\Phi)) \cup \Sigma), S', F' \vdash_{\theta}^{S''} G
 \end{array} \right\} \\
 \hline
 \Sigma, S, E \vdash_{\theta}^{S''} F \# \triangleright G \quad (9'a)
 \end{array}$$

The new rule has been augmented with:

- i. A test to determine if each non-policy program to be used in the new context is allowed by the current set of policy programs Σ . The test is done by invoking the predicate `valid_program/2` in $*\Sigma^{\circ}$ for each such non-policy program identified by `lw(Typei, URLi)` using a goal of the form:

$$\begin{array}{c}
 \emptyset, S, \xi \vdash_{\gamma}^{S'} * \Sigma^{\circ} \# \langle \text{valid_program}(\text{Type}1, \text{URL}1), \dots, \\
 \text{valid_program}(\text{Type}N, \text{URL}N) \rangle
 \end{array}$$

N is the number of program identifiers in $\text{expids}(F') \setminus \text{ids}(\Phi)$. A LogicWeb goal is used when evaluating the `valid_program/2` goals in order to download the policy programs. Note that goal evaluation fails if not all the policy programs are downloaded. Also, a policy program can invoke non-policy programs in its rules, and the evaluation of the `valid_program/2` goals begins with an empty policy program set. The rule for the case where Σ is empty is given below.

Note that we test all the programs in $F' = \text{insertCC}(F, E)$ instead of F , which means that we test the programs in the current context as well.

- ii. An extension of Σ with new policy programs. New policy programs are added to the front (left) of the ordered set Σ :

$$\text{pols}(I \setminus \text{ids}(\Phi)) \cup \Sigma$$

The last (rightmost) program in the ordered set is, chronologically, the first policy program, and its significance is explained below.

The following variant of the context switching rule caters for when Σ is empty. In that case, no policy programs are employed, no checks are made:

$$\begin{array}{c}
 I \subseteq \text{ids}(S') \quad \wedge \quad \text{pols}(I \setminus \text{ids}(\Phi)), S', F' \vdash_{\theta}^{S''} G \\
 \hline
 \emptyset, S, E \vdash_{\theta}^{S''} F \# \triangleright G \quad (9'b)
 \end{array}$$

In (i), we applied `valid_program/2` to all the programs used in the goal's program expression *and* all the programs in the current context. We illustrate why by considering an example:

```
valid_program(get, 'A').
valid_program(get, 'B').
valid_program(get, 'C') :- fail.    % may be omitted but added for clarity
```

If the goal $((A+B)*C)\#>G$ is used in A then we would expect it to fail since A is not permitted to use B in context switching. Suppose instead that the goal was $((\#)*C)\#>G$ and the current context (as represented by $\#$) was A+B. The goal is equivalent to the earlier one; should it be permitted or not?

If the goal is analysed by testing only C and ignoring the current context, then A would be allowed to use B in context switching, so violating A's policy. However, this behaviour appears harmless since B must already have been retrieved if it is in the current context, and so its utilisation will require no additional resources.

This would not be the case if the semantics of *add_programs* in Definition 2.2 were different. Suppose that A's use of B did result in the retrieval of a new version of B, then resources would be used. Or suppose that programs are only retrieved when their clauses are actually needed, and so B may not have been retrieved at the time of G's evaluation.

By conservatively testing the current context, we stay faithful to A's policy: A cannot use B via context switching, regardless of whether B is downloaded. This design is more general since it makes the security model more tolerant of changes in the system's download and storage mechanisms. Also, the intention of A's policy is arguably to unconditionally bar A from using B via context switching.

We could easily implement the less conservative view: namely that A cannot use B via context switching, unless B is already downloaded (or in the current context). A's policy program would become:

```
valid_program(get, 'A').
valid_program(get, 'B').
valid_program(get, 'C') :- program_exists('B').
```

`program_exists/1` is a LogicWeb built-in which succeeds if the specified program is in the local cache.

7.3 System Call Rules

Two new rules called *system call rules* are added to specify how policy programs are utilised with system calls. The first rule specifies a test to determine if a goal is a valid system call. It invokes `call_system/1` in the last policy program in Σ , which is the policy for the main program of the application. This means that any state changes carried out by `call_system/1` (for instance, see the example in §5.1)

will be done in the main program's policy program.

$$\begin{array}{c}
\Sigma \neq \emptyset \quad \wedge \\
\emptyset, S, \xi \vdash_{\gamma}^{S'} * \Sigma^{\#} \# \text{valid_systemCall}(G) \quad \wedge \\
\Sigma = \Sigma' \cup P_n \quad \wedge \\
\frac{\emptyset, S', \xi \vdash_{\theta}^{S''} P_n \# \text{call_system}(G)}{\Sigma, S, E \vdash_{\theta}^{S''} G} \quad (10'a)
\end{array}$$

Substitutions resulting from calling `valid_systemCall/1` are discarded. Instead, the substitutions computed from `call_system/1` are kept. As before, proofs occurring in policy programs proceed with an empty policy program set.

For the case where $\Sigma = \emptyset$, the rule is

$$\frac{\emptyset, S, E \vdash_{\gamma}^{S'} \text{built_ins}:\text{builtin}(G) \quad \wedge \quad \emptyset, S', E \vdash_{\theta}^{S''} \text{built_ins}:\text{call_builtin}(G)}{\emptyset, S, E \vdash_{\theta}^{S''} G} \quad (10'b)$$

A call to a built-in predicate in the module `built_ins` is represented by:

$$\frac{G \text{ succeeds with } \theta}{\emptyset, S, E \vdash_{\theta}^S \text{built_ins}:(G)} \quad (11)$$

The evaluation of the goal is outside the scope of the inference rules, but θ is assumed to be the computed answer substitution.

7.4 Properties of the Inference Rules

We show how the inference rules disallow illegal system operations. First, *context sequence* and *illegal system operation* are defined.

Goal derivation involving LogicWeb goals may result in several sequences of context switches, each represented by a sequence of contexts. For example, the sequence of contexts in Figure 5 is:

A, B, C

Note that the only operational semantic rules which change the context are the context switching rules (i.e. 9'a and 9'b).

Definition 7.3 (context sequence)

Given a sequence of applications of inference rules in a top-down derivation, suppose that there are $n - 1$ applications of the context switching rules. Further suppose that the i th application of these rules causes the context to switch from E_i to E_{i+1} , where $1 \leq i \leq n - 1$. The *context sequence* is the sequence of contexts E_1, \dots, E_n .

Informally, given a context sequence E_1, \dots, E_n , an illegal system operation is performed in the context E_i if a system call, or the use of a program in context switching, is disallowed by the policy of some program in E_i , but is attempted in E_i or some later context.

Definition 7.4 (illegal system operation)

Given a context sequence E_1, \dots, E_n , for some E_i , $P \in \text{pols}(\text{expids}(E_i) \setminus \text{ids}(\Phi))$,

$i \leq j \leq n$, and system call G , an illegal system operation is performed in E_i if the goal $\text{call_system}(G)$ is invoked when the context of G is E_j but $\emptyset, S, P \vdash_{\theta}^{S'} \text{valid_systemCall}(G)$ does not hold for any S, S' , and θ , or the oracle function is called on the identifier $\text{lw}(\text{Type}, \text{URL})$ when the current context is E_j but $\emptyset, S, P \vdash_{\theta}^{S'} \text{valid_program}(\text{Type}, \text{URL})$ does not hold for any S, S' , and θ .

The context switching rules guarantee that all policy programs which must be consulted during a derivation are present.

Lemma 7.1

Given the context sequence E_1, \dots, E_n for a top-down derivation, for any $i \in \{1, \dots, n\}$, at the node with context E_i , the current set of policy programs Σ contains the policy programs of all the non-policy programs occurring in E_1, \dots, E_i .

Proof

The proof is by induction on i . For $i = 1$, the goal evaluation starts in the empty program ξ with $\Sigma = \emptyset$. For $i \geq 2$, (by the inductive hypothesis) when the goal is evaluated in E_{i-1} , Σ contains the policy programs of all the non-policy programs occurring in E_1, \dots, E_{i-1} . E_{i-1} changes to E_i using one of the context switching rules. This rule updates Σ (say, to Σ') by adding to Σ the policy programs of the non-policy programs occurring in E_i . Hence, the goal evaluation continues in E_i with Σ' containing all the policy programs for the non-policy programs in E_1, \dots, E_i . \square

The theorem below implies soundness of the security model: all goals which have a successful derivation have the desired security property of not performing an illegal system operation.

Theorem 7.1 (safety property)

No illegal system operation is performed in any context during a top-down derivation using the above rules.

Proof

Given the context sequence E_1, \dots, E_n , for any $i \in \{1, \dots, n\}$, suppose that an illegal system operation was performed in E_i , say when the current context was E_j , where $i \leq j \leq n$, the set of policy programs was Σ , and the set of created programs was S . To perform this operation either (1) the system call rule for $\Sigma \neq \emptyset$ or (2) the new context switching rule for $\Sigma \neq \emptyset$ must have been used. In case (1), according to the definition of the system call rule used, since $\text{call_system}(G)$ was invoked, the goal:

$$\emptyset, S \cup \Sigma, * \Sigma^{\Theta} \vdash_{\gamma}^{S'} \text{valid_systemCall}(G)$$

must have succeeded. In case (2), suppose that the LogicWeb goal was $F\#>G$ and $F' = \text{insertCC}(F, E_j)$, and the oracle function was called on the identifier $\text{lw}(\text{Type}, \text{URL}) \in \text{expids}(F') \setminus \text{ids}(\Phi)$, then according to the definition of the context switching rule used, the goal:

$$\emptyset, S \cup \Sigma, * \Sigma^{\Theta} \vdash_{\gamma}^{S'} \text{valid_program}(\text{Type}, \text{URL})$$

must have succeeded. But by the definition of an illegal system operation, for some $P \in \text{pols}(\text{expids}(E_i) \setminus \text{ids}(\Phi))$, in case (1), $\emptyset, T, P \vdash_{\theta}^{T'} \text{valid_systemCall}(G)$ does not hold for any T , T' , and θ , and in case (2), $\emptyset, T, P \vdash_{\theta}^{T'} \text{valid_program}(\text{Type}, \text{URL})$ does not hold for any T , T' , and θ . In either case, it must have been that $P \notin \Sigma$. By the above lemma, Σ contains the policy programs of all the non-policy programs occurring in E_1, \dots, E_j , namely, $\Sigma \supseteq \text{pols}(\text{expids}(E_i) \setminus \text{ids}(\Phi))$. This means $P \in \Sigma$, and hence there is a contradiction. \square

8 Implementation

8.1 Interpreter with Security Mechanisms

The inference rules presented above provide the basis for an interpreter for evaluating goals in the presence of policy programs. Program 1 shows this interpreter, which is an extension of the one described in (Loke & Davison, 1998b).

`demo/3` is derived from a standard vanilla Prolog meta-interpreter (Sterling & Beer, 1989; Sterling & Shapiro, 1994), and executes a goal (the third argument of `demo/3`) against its program context (the second argument). The first argument of `demo/3` stores the IDs of downloaded policy programs.

In the first clause of `demo/3`, `establish_context/6` returns the new policy program identifiers for the programs in the new context.

The second clause checks for and invokes an allowed system call. In `allowed_systemCall/2`, `valid_systemCall/1` is invoked in each policy program. Policy programs known to the system are recorded in `pgpID_to_policyID/2`, which is described below. `invoke_systemCall/2` invokes the system call in the last program mentioned in the list of policy program identifiers (PL). This is the policy program for the main program, as mentioned earlier.

The third clause of `demo/3` allows policy programs to invoke goals in the Prolog module `built_ins`.

The last three clauses of `demo/3` implement the basic meta-interpreter. `select_clause/3` in the final clause evaluates the goal A by looking for a suitable clause ($A :- B$) from the programs defined by the program expression E . The clauses of downloaded programs are held in the program store (see Figure 2) in the format `lw(Type, URL) :: (Clause)`.

The interpreter is called using a goal such as:

```
?- demo([], empty, lw(get, "http://main.program")#>query).
```

Goal derivation begins with the empty context without any policy programs and a goal where `lw(get, "http://main.program")` is the main program of an application.

`establish_context/6` carries out several tasks. One of these is to expand the program expression F (which was part of a context switching goal $F\#>G$), so that any context operators ($\#$) in F are replaced by the current context. This results in a new program expression $F1$. Note that two copies of the original list of policy

```

% demo/3 with LogicWeb goal
demo(PL, E, F#>G) :-
    establish_context(PL, F, E, PL, NPL, F1),
    demo(NPL, F1, G).
demo(PL, E, G) :-
    allowed_systemCall(PL, G), invoke_systemCall(PL, G).
demo(_PL, P, built_ins:G) :-
    pgpID_to_policyID(_, P), call(built_ins:G).
demo(_PL, _E, true).

```

Program 1: The interpreter for pure LogicWeb programs which use policy programs.

programs is passed into `establish_context/6` initially. The fourth and fifth arguments of `establish_context/6` represent the current extended list and the newly extended list respectively. Because the current extended list may not be the original and the security tests are done using the original, the extra copy is supplied.

The last two clauses of `establish_context/6` relate to the security model. The penultimate clause checks a new program ID against the existing policies, and may download a new policy for that program, which causes the list of policies IDs (PL) to be extended.

```

```

Program 1: (Continued)

`allowed_program/2` checks a program ID (`lw(T,U)`) against the existing policies by calling `valid_program/2` against each policy in turn. This mimics the LW-intersection of LW-encapsulated policies described earlier.

`add_policyID/3` attempts to retrieve a policy ID for the specified program ID (`lw(T,U)`), and add it to the policy IDs list. This process is complicated by the possibility that the program ID may actually be a policy ID, which is ascertained

by checking it against `pgpID_to_policyID/2`. However, if `lw(T,U)` is an ordinary LogicWeb program ID, then `policyID/2` will contain a mapping from the program ID to its matching policy ID. How this is achieved will be explained shortly.

The final clause of `establish_context/6` checks all the programs in the current context against the existing policies. This check is required only once, but for simplicity, we have permitted the code to perform this check every time a context operator (`#`) is encountered in a program expression.

8.2 Installing Programs

The predicate for downloading a page and installing its corresponding LogicWeb program is given below. Its operation parallels the stages shown in Figure 3.

```
download(Type, URL) :-
    created(Type, URL), !.                % program already exists
download(Type, URL) :-                  % program does not exist
    retrieve(Type, URL, Contents),        % retrieve from the Web
    create_program(Type, URL, Contents),  % create the program
    assign_policyID(Type, URL, Contents). % assign a policy program
```

If the program stored at URL is not already present in the program store then its page is retrieved from the Web, converted to a program, and assigned a policy.

The policy mechanism is located in `assign_policyID/3`, which is defined as:

```
assign_policyID(Type, URL, Contents) :-
    (pgpID_to_policyID(_, lw(Type, URL)) ->      % if policy program
     true                                         % lw(Type, URL) is not assigned a policy program
    ;
     determine_policyID(URL, Contents, PolicyID),
     record_policyID(Type, URL, PolicyID)
    ).

determine_policyID(URL, Contents, PolicyID) :-
    (pgp_signed(URL) ->                          % if digitally signed
     authenticate(Contents, PGPID), % try authentication
     pgpID_to_policyID(PGPID, PolicyID)
    ;
     pgpID_to_policyID(unknown, PolicyID)
    ).

record_policyID(Type, URL, PolicyID) :-
    assert(policyID(lw(Type, URL), PolicyID)).
```

`assign_policyID/3` tries to obtain a security policy for a downloaded (non-policy) LogicWeb program by calling `determine_policyID/3`. It bases its search on the result of calling `pgp_signed/1` which checks if the contents of the downloaded page are digitally signed. It does this by inspecting the URL for the extension “`.lwpgp.html`”, which denotes a digitally signed LogicWeb program.

If the program is signed then the signature is authenticated with `authenticate/2`. It invokes PGP’s authentication procedure on `Contents`, which contains the HTML text and its digital signature. This stage is depicted in Figure 3

in box B. PGP extracts the digital signature from `Contents`, and attempts to decrypt it to obtain an MD5 string by employing its collection of public keys. These keys must have been previously added to PGP by the LogicWeb administrator. On successful decryption, PGP checks the HTML text from `Contents` against the MD5 string, and returns the PGP ID labelling the key that decrypted the signature as `PGPID`. On authentication failure (i.e., if the signature is not decrypted or if the MD5 string does not match the HTML text), `PGPID` is instantiated to `unknown`.

The signature ID returned by `authenticate/2` is utilised by `pgpID_to_policyID/2` to lookup a policy ID. A typical `pgpID_to_policyID/2` fact:

```
pgpID_to_policyID('Seng W. Loke <swloke@cs.mu.oz.au>',
                  lw(get, "http://www.cs.mu.oz.au/~swloke/my_policy.html")).
```

The first argument is Seng Wai Loke's PGP ID, and the second a policy program identifier.

If the downloaded LogicWeb program is not signed then `determine_policyID/3` makes use of the default policy ID associated with the 'unknown' signature ID:

```
pgpID_to_policyID(unknown,
                  lw(get, "http://www.cs.mu.oz.au/~swloke/default_policy.html")).
```

Back in `assign_policyID/3`, the policy ID returned by `determine_policyID/3` is passed to `record_policyID/3`. It asserts a `policyID/2` fact which has as its first argument the LogicWeb program ID and its second is the matching policy ID. This fact can be used subsequently to map from a program ID to its policy. The fact is not asserted into the LogicWeb program itself since it must be impossible for a rogue program to redefine `policyID/2`.

9 Control of Resource Usage

This section considers denial-of-service attacks by showing how it is possible to control an operation or resource with policy programs and meta-interpreters.

9.1 Resource Control Using Policy Programs

Resource usage can be monitored by keeping contextual or state information within a policy program, allowing decisions about the utilisation of resources to be based on the execution history. For example, a limit can be imposed on the frequency of system calls.

The following definition of `call_system/1` permits up to ten files to be opened at a time, thereby limiting the number of allocated file descriptors.

```

call_system(P) :-                                % for non- open/3, close/1 calls
    P \= open(_, _, _),
    P \= close(_),
    built_ins:call_builtin(P).
call_system(open(F, R, S)) :-                    % open a file
    open_count(N), N < 10,
    increment_open_count,                        % increment count of open files
    built_ins:call_builtin(open(F, R, S)).
call_system(close(S)) :-                        % close a file
    open_count(N), N > 0,
    decrement_open_count,                       % decrement count of open files
    built_ins:call_builtin(close(S)).

```

increment_open_count/0 and decrement_open_count/0 update the value stored in open_count/1.

9.2 Resource Control Using Meta-interpreters

As pointed out in (Ousterhout *et al.*, 1997), denial-of-service attacks are not as severe as other kinds of attack since the user can always hit the “kill key” and exit the system. However, the graceful termination of goal evaluation is preferable so that the system and application can at least continue running. Execution control can be readily incorporated into the system by using meta-interpreters (Sterling & Beer, 1989; Sterling & Shapiro, 1994). Their use for loop checking and detecting resource limits is described below.

9.2.1 Loop Checking

Our approach to loop checking uses two meta-interpreters. `solve_ad/2` evaluates a goal and also stores information about ancestor goals and the recursion depth. Program 2 shows a simplified version of `solve_ad/2` for pure Prolog.

```

solve_ad(_Depth_Ancs, true).                    % evaluate true
solve_ad(_Depth_Ancs, (G1, G2)) :-              % evaluate conjunction
    solve_ad(_Depth_Ancs, G1),
    solve_ad(_Depth_Ancs, G2).
solve_ad(_Depth_Ancs, Goal) :-                  % evaluate goal
    copy_term(Goal, CopyGoal),                  % make a copy of the goal
    clause(Goal, Body),                         % select a matching clause
    spy_point(_Depth_Ancs, Goal),               % insert a spy_point
    Depth1 is Depth + 1,                        % increment recursion depth
    solve_ad(Depth1-[CopyGoal|Ancs], Body).

```

Program 2: A meta-interpreter for pure Prolog with an argument carrying the recursion depth and a list of ancestor goals.

The purpose of the `spy_point/2` call will be explained shortly.

The `solve_t/2` meta-interpreter terminates goal evaluation whenever some pre-defined termination condition becomes true. Such conditions are specified as

`terminate/1` clauses. `solve_t/2` also sets a termination flag to ‘terminated’ when a termination condition becomes true. Program 3 shows a simplified version of `solve_t/2` for pure Prolog.

```
solve_t(true, _).           % evaluate true
solve_t(Goal, T) :-
    terminate(Goal), !,    % check termination conditions
    T = terminated.
solve_t((G1, G2), T) :-   % evaluate conjunction
    solve_t(G1, T),
    (T == terminated ->
        true
    ;
        solve_t(G2, T)
    ).
solve_t(Goal, T) :-       % evaluate goal
    clause(Goal, Body),
    solve_t(Body, T),
    (T == terminated, ! ; true).
```

Program 3: A meta-interpreter for pure Prolog which checks for termination conditions.

The next step is to combine these meta-interpreters with the LogicWeb `demo/3` interpreter described in the previous section. Instead of invoking `demo/3` directly, as in:

```
?- demo([], empty, LogicWebGoal).
```

it will be called nested inside the two meta-interpreters:

```
?- solve_t( solve_ad(0-[], demo([], empty, LogicWebGoal)), _T ).
```

`solve_ad/2` will record ancestor goals and recursion depth information about `demo/3`. `solve_t/2` can check for termination conditions by looking for suitable patterns in the `spy_point/2` calls in `solve_ad/2`. For example:

```
terminate(spy_point(Depth-Ancs, demo(_, E, G))) :-
(
    member(demo(_, E1, G1), Ancs),
    E = E1,                % the goals are in the same context
    variant(G, G1),        % and they are variants of each other
    write('loop found')
;
    Depth > 40,             % recursion depth too large
    write('maximum recursion depth exceeded')
).
```

`demo(_, E, G)` is the current LogicWeb interpreter goal, `Depth` is the current recursion depth, and `Ancs` is the list of ancestor goals. Note that the condition `E = E1` will not detect loops where the context grows indefinitely. To detect such loops, the size of the context can be compared against a preset limit.

The essential utility of this approach is the relative ease of combining distinct meta-interpreters which monitor/control different aspects of the computation. Other loop checking techniques are studied in (Bol, 1991).

9.2.2 Resource Limits

The techniques from the last section can be easily utilised to monitor resource limits. We will measure two resources: the number of LogicWeb programs downloaded, and the number of clause applications. The first count will persist across different `solve_t/2` invocations, the second will be reset at each invocation of `solve_t/2`.

The necessary `terminate/1` clauses for these measures are:

```

terminate(invoked_builtin(download(_,_))) :-
    program_count(N),
    N > 100,           % permit up to 100 program downloads
    write('maximum LogicWeb program count exceeded').
terminate(invoked_builtin(clause(_,_))) :-
    retract(clause_count(N)),
    N1 is N + 1,
    assert(clause_count(N1)),
    (N > 500 ->        % permit up to 500 clause applications
     writef('maximum clause count exceeded'))
    ;
    !,
    fail
    ).

```

This code assumes that `solve_ad/2` can deal with built-in predicates, which would require a minor extension to Program 2.

The first `terminate/1` clause monitors program downloads by looking for calls to the `download/2` built-in. When there is such a call, `program_count/1` is checked to see if the number of programs downloaded exceeds 100. If it does then execution is terminated. The use of `program_count/1` would require a change to `create_program/3` (called by `download/2`) which translates a page into a program; it would also have to increment `program_count/1` each time a new program was created.

The second `terminate/1` clause restricts the number of clause applications by monitoring calls to the `clause/2` built-in. The `terminate/1` clause increments the number stored in `clause_count/1` until it exceeds 500.

An oft-stated problem with nested meta-interpreters is the penalty incurred upon execution speed. In fact, the termination checks described here could be implemented more efficiently by directly modifying `demo/3`. However, multiple meta-interpreters are less complex to understand than a single, monolithic piece of code. Also, they permit a compositional approach to implementing execution control: functionality is separately implemented and introduced. We also believe that the speed costs are relatively unimportant if the application carries out frequent Web requests, and hence spends most of its wall-clock execution time interacting with the Web. Moreover, partial reduction techniques for translating meta-interpreters into specialised forms can be explored to remove the levels of interpretation (Sterling & Shapiro, 1994).

10 Comparisons with Security Models in Other Mobile Code Systems

We review security models which share certain common features with LogicWeb. First, we consider security approaches in some interpreted languages, and then examine systems which utilise policy modules and authentication.

10.1 Security Models in Two Interpreted Languages

10.1.1 Safe-Tcl

Tcl is an interpreted imperative language, and access to system resources is via permitted commands of the interpreter. In the Safe-Tcl security model (Ousterhout *et al.*, 1997), security is enforced by making dangerous commands unavailable to scripts running in the *safe interpreter*. Potentially dangerous operations, such as opening sockets, can be carried out via wrappers or aliases. The wrappers ensure that the commands are used in a controlled manner (e.g., only socket connections to some hosts are permitted).

The security model in LogicWeb is partly motivated by the Safe-Tcl approach: LogicWeb's valid system calls correspond to Safe-Tcl commands, and `call_system/1` corresponds to wrappers for those commands. A safe interpreter in Safe-Tcl corresponds to the LogicWeb program interpreter with appropriate policy programs. However, the Safe-Tcl security model has no notion of authentication.

Safe-Tcl allows programs running in different interpreters (each with its own security policy) to communicate. Such communication effectively composes the security policies of the programs, i.e. a program can use the privileges of other programs. The dangers of this are highlighted in (Ousterhout *et al.*, 1997), but not solved in a structured way. In LogicWeb, the composition of policies do not violate safety criteria.

10.1.2 Java Applets

A Java applet is transmitted in bytecode format, and then executed by an interpreter on the local host. This contrasts with Safe-Tcl and LogicWeb where source code is transferred.

The LogicWeb system does not support concurrency or sophisticated GUI programming, and so its security model does not need to deal with multi-threading or screen resources (e.g., windows). The Java language enforces type safety by having the compiler ensure that class methods do not access memory in ways that are inappropriate for their type (Sun Microsystems, Inc, 1997). LogicWeb programs are not explicitly typed and there is no class abstraction. However, type conversions (e.g., strings to atoms) are done via system calls, and so the dangers of type conversion are avoided at call time. There are two trust levels for classes in the current Java security model: trusted classes are local and part of the Java system, while untrusted classes are ones that are downloaded. Multiple levels of trust are possible with signed LogicWeb programs.

Security for Java applets, as implemented in Microsoft's Internet Explorer 3.0

and Netscape Navigator 3.0, disallows applets from reading from or writing to local files, or establishing network connections except to the originating host. However, there are ways around these problems, including the use of server-side databases and proxy servers. The digital signing of JAR (Java ARchive) files, as supported in JDK 1.1.5², bundles Java code and related files together into one file (Sun Microsystems, Inc, 1997). In a similar way, a collection of programs making up a LogicWeb application can be bundled, signed, and transported as one archive file.

Microsoft Internet Explorer 4.0 now allows finer grained control over the capabilities granted to Java code, such as access rights to local files and network connections (Microsoft Corporation, 1999a; Microsoft Corporation, 1999b). This is done by including a list of capabilities requested by the applet in the applet's signature. Approval for the capabilities are either pre-set or given via user dialog. The implementation prevents transfer of privileges between classes in a similar way to our model: if a class has not been directly granted a capability, it cannot obtain that capability regardless of its caller's capabilities. A class without a capability cannot gain that capability by invoking a more privileged class.

10.2 Security Policy Modules in Two Mobile Code Systems

10.2.1 SERC's Safer Erlang (SSErl)

The security mechanism in LogicWeb was motivated by the policy modules used in SSErl, a functional declarative language for programming concurrent and distributed systems (Brown, 1997a; Brown, 1997b). In the SSErl framework, a policy module is not associated with a particular program as in LogicWeb, but with a SSErl node, a platform where multiple processes may run concurrently. System operations are performed via built-in functions. A policy module specifies the allowable built-in functions for all the processes running at a node.

In contrast to SSErl, execution of LogicWeb programs is single-threaded, although the thread of execution can proceed from one program to another. At any one time, at most one LogicWeb application is running. The overall policy for the running application is represented by the current set of policy programs, and is determined dynamically since it is generally not possible to determine *a priori* which programs an application will use.

10.2.2 Java Aglets

The Aglet workbench (Karjoth *et al.*, 1997) allows Java programs (called *aglets*) to be transferred between hosts as mobile agents. A specialised language for writing aglet security policy modules has been proposed which makes use of specific roles such as the aglet's manufacturer, owner, execution platform (e.g., the URL of the host), and domain. In the LogicWeb implementation, the assignment of policy programs is currently based solely on a program's signature (as implemented by `determine_policyID/3` in §8.2).

² JDK 1.1.5 (final version) is available at <http://java.sun.com/products/jdk/1.1/>.

10.3 Authentication in Two Mobile Code Systems

10.3.1 Agent Tcl

Programs are authenticated with PGP in Agent Tcl (Gray, 1996). PGP is invoked externally in the same way as in LogicWeb, thereby keeping the Agent Tcl system simpler and more flexible (the encryption mechanism can be easily replaced). Depending on the identity of the agent's owner, an Agent Tcl program is assigned resources such as CPU time, windows, the file system, external programs, and network connections.

10.3.2 ActiveX

ActiveX controls (Ernst, 1996) are programs (in native x86 code) that can be executed on the client-side in Web pages. A digital signature is attached to each ActiveX control which identifies the control's author. The advantage of a signature is that since the author is known, an ActiveX control is permitted more freedom to access resources.

Unlike a LogicWeb program, which is sandboxed by policy programs and meta-interpreters, a trusted ActiveX control is not restricted in any way and has access to all operating system services. Since an ActiveX control is native code, a suitable sandbox mechanism may be more difficult to implement (Object Management Group, 1999).

11 Summary and Future Work

Security is a major concern for any system that executes downloaded code. This paper has described a security model for LogicWeb which protects the client host from integrity, privacy, and denial-of-service attacks. The security model is specified using proof rules in the operational semantics of the language. This specification permits a straightforward proof of the soundness of the model with respect to illegal system operations. Resource control of predicates invoked at the application level is carried out using policy programs. Resource control of programs using resource counts and loop checking is performed by meta-interpreters. Authentication provides varying trust levels, and different policy programs define resource access for the different trust levels.

The security model dynamically extends the LogicWeb system with selected policy programs. Since policy programs are separate from the system (and integrated only on-demand) they are a convenient means for imposing consistent security restrictions on multiple hosts. For example, similar Intranet-wide security restrictions can be imposed on a group of hosts by having them download the same policy programs (which, if needed, can be specialised by being composed with host-specific policies).

As noted in (Ousterhout *et al.*, 1997), it may be difficult to distinguish between legitimate behavior and denial-of-service attacks. For instance, it is easy to introduce resource bounds but difficult to state appropriate values for those bounds. If a

value is too low, a useful task may be terminated prematurely; if too high, resource wastage occurs. A possible solution to this dilemma is to involve the user's judgment by providing query-the-user facilities via a meta-interpreter. The user could also utilise trace information supplied by the meta-interpreter to detect unwanted behavior, such as the movement of data between sites using the host's resources.

Some Prolog systems, such as SICStus Prolog, have a time-out facility for goal evaluation – the goal is terminated if its evaluation exceeds a given duration (Intelligent Systems Laboratory, Swedish Institute of Computer Science, 1996). This can be incorporated as a hard limit after other checks in our meta-interpreters:

```
?- time_out(solve_t(solve_ad(0-[], demo([], empty, LogicWebGoal)), _T),
           Time, Result).
```

`time_out/3` terminates the execution of `solve_t/2` after `Time` milliseconds, with `Result` being set to `timeout` or `success`.

Policy programs could be allocated based on the more general idea of credentials instead of digital signatures alone. For instance, a program might be allowed certain privileges not only because of its signature, but because it had sufficient advocates. Recent work by Seamons *et al* (1997) on using Prolog to encode digital credential acceptance policies and their verification logic could be exploited.

Policy programs simplify the administration of privileges to applications. Our policy assignment depends solely on the digital signature of the LogicWeb program. A more flexible method would involve multiple roles such as the program's manufacturer, owner, execution platform, or domain. For instance, suppose we trust particular domains (or URLs) and assume that data transfer is not intercepted and modified. We can assign policies based on the domains or URLs of the LogicWeb programs, regardless of whether they are signed. We modify `determine_policyID/3` of §8.2 as follows:

```
safe("http://www.cs.mu.oz.au/~swl").           % trusted URLs
safe("http://www.cs.ait.ac.th/~ad").

determine_policyID(URL, _Contents, PolicyID) :- % safe URLs get a standard policy
    safe(URL), !,
    PolicyID = lw(get, "http://www.policyforthe trusted.com").
determine_policyID(URL, Contents, PolicyID) :- % check signature for everything else
    (pgp_signed(URL) ->
        authenticate(Contents, PGPID),
        pgpID_to_policyID(PGPID, PolicyID)
    );
    pgpID_to_policyID(unknown, PolicyID)
).
```

Domain or zone-based policy assignment can be implemented this way.

LW-composition operators could be used to create policies from dynamically composed programs. For instance, assume that the program at `http://www.usedownloadedpgms.com` stores the clause:

```
valid_program(X) :- program_exists(X).
```

`determine_policyID/3` can be modified to always combine this policy with the one being downloaded:

```
determine_policyID(URL, Contents, Policy) :-
  (pgp_signed(URL) ->
    authenticate(Contents, PGPID),
    pgpID_to_policyID(PGPID, PolicyID)
  );
  pgpID_to_policyID(unknown, PolicyID)
),
Policy = lw(get,"http://www.useddownloadpgms.com")+PolicyID. % combine policies
```

We have only considered policy programs created by the user of the LogicWeb system. If policies could be created by other parties, authentication would then become necessary for policy programs in addition to ordinary LogicWeb programs.

A limitation of our model is that the system must contain all the public keys required for the authentication of incoming programs. An automatic distribution mechanism for PGP public keys is needed. For example, the LogicWeb system could extract required public keys from homepages given their URLs, or could query Internet PGP public key servers³ (Garfinkel, 1995). But this requires that the information be trusted, has not been tampered with, and is reliable. The use of credentials, i.e. certification by other authorities, would be required.

The LogicWeb security model is conservative in that a trusted program is not allowed to transfer its privileges to an untrusted program it is using. Besides resource usage privileges, another kind of privilege could be introduced: the right to transfer privileges. This would be useful when the system did not know the signatories of all the programs that a trusted program utilised. The policy program would have to specify which privileges were transferable, and whether the right to transfer privileges was itself transferable.
